Population Covered By The Guidance

This pathway provides guidance on imaging patients with chronic dyspnoea.

Quick User Guide

Move the mouse cursor over the PINK text boxes inside the flow chart to bring up a pop up box with salient points. Clicking on the PINK text box will bring up the full text. The relative radiation level (RRL) of each imaging investigation is displayed in the pop up box.

Pathway Diagram
Teaching Points

- Chronic dyspnoea is defined as dyspnoea lasting more than one month
- Plain chest radiography provides useful information in the majority of cases to justify its routine use
Indications for CT / HRCT include

- Restrictive lung disease
- Preoperative assessment of patients who are being referred for lung reduction surgery
- Patients who have dyspnoea and reduced single-breath diffusing capacity for carbon monoxide without evidence of airflow obstruction
- Patients with chronic dyspnoea in whom the initial evaluation (clinical assessment, CXR and pulmonary testing) is non diagnostic or non revealing

**Chronic Dyspnoea**

- Defined as dyspnoea lasting for more than one month and can be caused by a wide range of conditions
- Over two thirds of cases are caused by pulmonary or cardiac aetiology with the most common causes being asthma, interstitial lung disease, COPD and myocardial dysfunction
- The history and examination will usually provide clues to the underlying diagnosis and direct investigation

**Cardiac Dyspnoea**

- Cardiac dyspnoea or cardiovascular dyspnoea includes causes of dyspnoea which relate to the cardiac pump and its associated vasculature. It is common to have combined cardiac and other causes of dyspnoea co-existing in a patient especially along with the pulmonary causes. Cardiac dyspnoea is generally evaluated with electrocardiography, laboratory blood tests (N-Brain natriuretic peptide), echocardiography, Holter monitoring, cardio-pulmonary exercise testing and cardiac catheterisation

**Electrocardiography**

- Easily available, non-invasive, inexpensive and quick
- Can show abnormalities in heart rate and rhythm and in addition can detect cardiac ischemia, chamber enlargement and pericardial diseases

**Holter Monitoring**

- A 24 hour or sometimes up to 72 hour recording of heart rhythm in cases suspected for arrhythmias is another inexpensive, relatively readily available and a non-invasive test

**Brain Natriuretic Peptide (BNP)**

- Blood test, relatively quick and obtainable
- BNP is a hormone present in cardiac musculature especially ventricles. BNP is released when the ventricles are under tension as occurs in heart failure and this can be used as a predictor of the presence as well as to estimate the severity of the failure based on the levels of BNP in the test sample

**Echocardiography (Echo)**

- Relatively easily available, relatively quick. No radiation involved
Trans-thoracic echocardiography is non-invasive whereas trans-oesophageal echocardiography is invasive.

Echo is the most widely used imaging modality to investigate cardiac failure. Can detect both right and left heart failure, valvular heart diseases and pericardial diseases. Stress echo test can be used to detect cardiac ischemia. Colour flow Doppler echo can be used to detect chronic thromboembolic disease and pulmonary hypertension.

In one study it was noted that 2/3rd of elderly adults with unexplained dyspnoea after history, physical examination, chest radiograph and lung function tests had diastolic dysfunction on echocardiography.

Cardio-pulmonary exercise testing (CPET)

Cardio-pulmonary exercise testing is an advanced physiological multi-system testing modality which is relatively non-invasive but less widely available compared to the above tests.

CPET is usually done in cases with high clinical suspicion but equivocal test results or in whom multiple causes may co-exist for dyspnoea and is also very useful in detecting deconditioning and primary hyperventilating syndromes.

Chest Computed Tomography (CT)

Use of helical multi-detector CT with thin collimation instead of conventional high resolution CT has the advantage of contiguous data acquisition, but at a significantly higher radiation dose. However, studies with MDCT for conditions causing chronic dyspnoea have not been widely published in the literature as yet.

Choice of scanning technique depends on the clinical scenario and the age of the patient. Younger patients (especially females) should have HRCT if clinically acceptable.

Interstitial Lung Disease

HRCT uses narrow 1-2mm collimation (section thickness) every 10-20mm throughout the thorax. While effectively only 10% of the lung is imaged, this a sufficient sample to detect the diffuse parenchymal abnormalities which characterise ILD and minimises the radiation dose delivered to patients.

HRCT features of usual interstitial pneumonia (the radiopathological pattern associated with idiopathic pulmonary fibrosis) include irregular reticular lines, traction bronchiectasis, irregular lines and honeycombing in a basilar distribution.

Overall HRCT has high sensitivity 77-79% and specificity 72-90% with a positive predicted value of 85-88% in diagnosing IPF when compared with histological specimens obtained at lung biopsy as the gold standard.

The sensitivity, specificity and PPV of a confident radiological diagnosis of IPF (ie. when uncertain cases are excluded) rises to 87%, 95% and 96% respectively.

The sensitivity and specificity of ILD other than IPF is significantly lower at 59% and 40% respectively.

Based on the studies above, surgical lung biopsy remains the gold standard for accurate diagnosis of ILD when the diagnosis is uncertain, and when the clinical diagnosis is and ILD other than IPF.

Emphysema
Superior to plain radiography in showing the presence, distribution and extent of emphysema. Although conventional or spiral CT can detect most cases of emphysema, HRCT is more reliable. Emphysema is characterised by areas of abnormally low attenuation on HRCT. Mild early emphysematous change may be missed on HRCT (low sensitivity), however it is still superior to pulmonary function testing in detecting the presence of emphysema and correlating with the severity of disease. The grading of emphysema based on HRCT findings correlated well with pathological severity in several studies and is in the order of 0.7-0.9. The role of CT in the clinical assessment of emphysema is limited by its expense. The main indications for the use of CT in assessing emphysema are:

- Preoperative assessment of patients who are being referred for lung reduction surgery.
- Patients who have dyspnoea and reduced single-breath diffusing capacity for carbon monoxide without evidence of airflow obstruction.

Non-specific Abnormalities

- CT scanning should be considered in patients with chronic dyspnoea when the initial evaluation (clinical assessment, chest radiography and pulmonary testing) is non-diagnostic or non-revealing.
- This should be weighed against the radiation exposure risk, particularly in young patients.

Chest Radiograph

- Can reveal enough useful information regarding the diagnosis to justify its routine use in the initial investigation of chronic dyspnoea.
- Used to exclude or demonstrate obvious chest wall abnormality (e.g. severe kyphoscoliosis, pectus excavatum) and/or help direct further investigations.
- One study found a positive predictive value of 75% and negative predictive value of 91% in the diagnosis of all causes of chronic dyspnoea.
- Plain radiography had a sensitivity of 97% in diagnosis of symptomatic patients with moderate to severe emphysema based on radiological signs of hyperinflation and vascular alterations. However, its usefulness in diagnosis of mild emphysema is limited with low sensitivity and specificity.
- Although chest radiography may be normal in patients with chronic dyspnoea due to interstitial lung disease, one study found interstitial changes on plain film in all 12 of their patients who had ILD.
